CLIVAR PPAI Panel Discussion
Diurnal Cycle of Convection
Basis for generation of precipitation

Convective clouds form over the mountains in the morning.

By afternoon and evening storms propagate to the west towards the Gulf of California where they can organize into mesoscale convective systems if there is sufficient moisture and instability.

It’s likely that a resolution less than 5 km, or alternatively superparameterization, is necessary to represent this process correctly in regional models. Global models pretty much fail.

Nesbitt et al. (2008, *J. Hydrometeor.*)
Figure 10: Cross sections of WRF model simulated radar reflectivity (dBZ) (left panels) on domains 2 and 3 with corresponding zonal and vertical wind velocities (m s\(^{-1}\)) and m s\(^{-1}\), respectively) (center and right panels) at 0300 UTC 14 July. Wind vectors on radar reflectivity panel are scaled such that the horizontal wind is ten times larger than the vertical wind. The vertical planes to construct the cross section are defined intersecting a point at 29.69° N and 111.4° W and extending along constant latitude from 112.5° W to 107.5° W, and the frames have a height of about 20 km. They are averages of parallel planes north and south of the center and extend through the depth of the model.
Model precipitation biases in WRF: downscaled NCEP reanalysis and CFSv1

Systematic problems in the climatological representation of rainfall that are clearly terrain-dependent. Similar problems in other RCMs.

Reflects the fact that the RCM is challenged to represent organized, propagating convection, irrespective of the driving GCM.

This type of convection varies on an intraseasonal timescale and accounts for more precipitation away from the mountains.

Ciancarelli et al. (2013, Int. J. Climatol.)
Boreal warm season atmospheric teleconnections
Per classifications of Ding et al. (2011, *J. Climate*)

**Western Pacific North America Pattern (WPNA)**

**Circumglobal Teleconnection (CGT)**

**ENSO/PDV Forced: Early summer (JJ)**
- Probably most seasonally predictable

**Indian monsoon forced: Late summer (JAS)**

Figure 14. (a) Idealized atmospheric teleconnection pattern associated with JJ REOF 1 (ENSO/PDV forcing dominant). (b) Idealized atmospheric teleconnection pattern associated with AS REOF1 (likely dependent on Asian monsoon convection). Wet/dry areas over the United States indicated by blue/red.

Figure 15. (a) Cartoon illustrating the CGT atmospheric teleconnection pattern associated with JJ REOF 2 (likely associated with the CGT). (b) Cartoon illustrating the CGT atmospheric teleconnection pattern associated with JJ REOF 5 (likely associated with the CGT). Wet/dry areas over the United States indicated by blue/red.

Ciancarelli et al. (2013, *Int. J. Climatol.*)
Influence of Atlantic Multidecadal Oscillation
e.g. Hu and Feng (2011, *J. Climate*)

**Fig. 1.** (a) North Atlantic Ocean surface temperature anomalies in the warm phase of the AMO, and (b) as in (a), but for cold phase (unit: °C). The SST anomalies are inflated by 2 times to amplify the signal to noise ratio and allow for clear dissection of causal mechanisms.
Warm phase: Weaker North Atlantic subtropical high, weaker Great Plains low-level jet.

Dry in central U.S., wet in Southwest U.S.

Cold phase: Stronger North Atlantic subtropical high, stronger Great Plains low-level jet.

Wet in central U.S., dry in Southwest U.S.

Probably synergistically interacts with ENSO-PDV forced variability.

Hu and Feng (2011, J. Climate)
Most of these types of studies explore this hypothesis in a statistical framework only.

The alternative hypothesis of atmospheric teleconnection mechanisms previously presented is also supported by idealized dynamical modeling.
Antecedent Precipitation (JFM) Anomalies associated with early and late monsoons in northwest Mexico

Zhu et al. (2007, *J. Climate*)

Resembles classic ENSO-type signature for winter precipitation variability in North America
Current warm season seasonal forecast skill in North American Multimodel Ensemble (NMME)

**Fig. 9.** Precipitation forecast RPSS for the (a) grand NMME multimodel ensemble and for (b) CFSv2. The skill is based on hindcasts initialized in Jan 1982–2009 and verified in the following JJA seasonal mean for tercile forecasts. Positive values indicate probabilistic skill that is better than climatology, and negative values indicate probabilistic skill that is worse than a climatological forecast. Global-averaged RPSS is noted in the figure.
Are skillful seasonal NAMS forecast possible?

Castro et al. (2012, *J. Climate*)

Global seasonal forecast models, such as the Climate Forecast System model used by U.S. Climate Prediction Center do have an ability to statistically represent WPNA response and its impact on warm season precipitation.

For skillful NAMS forecasts, a seasonal forecast GCMs must have an ability to deterministically represent warm season atmospheric teleconnections.
Observed Change in Early and Late Warm Season Climatology: 1980-2010 minus 1950-1980

Chang et al. (JGR, accepted)

Recent observational record seems to comport with “wet gets wetter, dry gets drier idea”

Ensemble mean JA projected precipitation change (%) of NARCCAP models and degree of confidence
Bukovsky et al. (2015, J. Climate)

Considering the core NAMS region, the change in precipitation is slightly negative.

But this decrease is relatively small and there is little agreement among the NARCCAP models.
Note in some cases there can be differences in the sign of precipitation projections among RCMs even when forced by the same CMIP3 GCM.

Bukovsky et al. (2015, *J. Climate*)
Improved North American monsoon precipitation in CMIP5 models
Cook and Seager (2013, J. Geophys. Res.)

Figure 2. Comparison of precipitation climatologies (1980-1999) for the core NAM region in the CMIP5 historical simulations (dashed lines) and the GPCC precipitation data (grey line). Lowest resolution models are shown in (a), highest resolution models are displayed in (b). Where multiple ensemble members were available, the model climatologies represent ensemble averages.
Ensemble mean changes in North American Monsoon Precipitation in CMIP5 models
Cook and Seager (2013, J. Geophys. Res.)

Decreases in precipitation during early summer due to enhanced atmospheric stability, under more intense monsoon ridge.

Increases in precipitation in late summer and early fall once stability barrier can be overcome.
What causes extreme precipitation in the West?

Ralph et al. (2011)
Technical Approach
Dynamical downscaling to address severe weather question

Yields climate change projection results that simulate possible changes in extreme events in a physically-based way, using a well-established modeling paradigm for weather forecasting.
Panel issues

How should the NMME reforecast (and other similar) products be used to evaluate warm season skill? Should there be some distinction between the large-scale atmospheric circulation and surface temperature and precipitation?

What are physically based metrics that could be applied to climate prediction and projection models (e.g. NMME and CMIP) that could be used as differential weighting in creating ensemble averages?

It is well recognized in weather forecast community that convective resolving scale (or superparameterization) is essential for the warm season to reasonably simulate organized convective structures. How do we adapt this paradigm for climate forecasts/projections in a way that is computationally feasible?

Do we need a community MRED Phase II experiment to evaluate the value added of regional modeling with use of the NMME reforecast data? What kinds of procedures and metrics would be appropriate for an effort of this type?
